## PREFACE

The pressing need to produce more electrical energy by fossil fuelled power plants with a greater use of coal may result in increased mobilization of heavy metals by fossil fuelled power plants with increased contamination hazard for man and environment.

Because of the complexity of the possible interactions between heavy metals with environment as well as man, the nature of the risks that the toxic metals mobilized by fossil-fuelled power stations represent is problematic and involves multidisciplinary efforts to establish dose-effect relationships which could serve as a basis in determining maximum permissible release rate for the environment and maximum permissible doses for man.

Research reports of the JRC on this subject have been divided into a series of five reports with the purpose of examining and evaluating critically the available data giving a list of topics which may serve as a guide-line for a research project which should be undertaken to study the EC situation. They are:

Mobilization of heavy metals from fossil-fuelled power plants, potential ecological and biochemical implications

- I    Electricity demand, installed capacity and geographical location of the fossil-fuelled power stations in the territory of the European Community;
- II   Definition of the problem using a critical path approach, motivation, objectives and research programme to study the European situation;
- III   Heavy metal content in coals burnt in the European power plants;
- IV   Assessment studies of the European situation;
- V   Natural radionuclides in coals and coal ashes from European conventional power stations and evaluation of a potential environmental impact.

This work is the first of the series and provides technical basis for the calculations of the minimum and maximum amounts of heavy metals which may be annually mobilized by the conventional power plants of the European Community.

## INTRODUCTION

For the assessment of the mobilization of heavy metals from fossil-fuelled power plants operated in the territory of the European Community (EC) basic data on electricity production by conventional thermal power plants are required.

The present report gives a short outline of statistics on electricity production in the countries of the EC for the last 10 years laying emphasis on conventional thermal power plants. Data on the amount of electricity produced and kind and quantities of fuels burnt by the power plants of the single member states are reported.

The conventional thermal power stations situated in the EC are listed and their geographical location is shown by separated maps for each member state.

### 1. Electricity production in the European Community

In 1978, electricity consumption in the European Community has been 1,082,000 GWh. In comparison with 1977, this means an increase of the demand of 4.2%. Variation in electricity demand for 1977 in respect to 1976 has been 3.2% (1).

Figure 1 shows the total electricity generation of the countries of the European Community during the last 18 years. From 1960 to 1973, growth in electricity production was characterized by a doubling time of 10 years with a little bend in the only 1967. Period from 1973 to 1977, however, shows a much lower increase of electricity production, namely of an average of 2.3% per year, which corresponds to a doubling time of about 30 years.

For the first time after the second world war, a decrease (- 1.8%) in electricity production in the countries of the European Community happened in 1975.

Again in the beginning of 1975, forecastings by the Commission of the European Community of 30.1.75 (2) predict on average annual growth rate of 7.2% for the period between 1975 and 1980, of 7.9% for the period from 1980 to 1985, and of 8.7% for the period from 1985 to 1990.

The expected gross electricity generation for 1980 should be 1640 TWh, for 1985 2400 TWh and for 1990 3650 TWh, whereby about 1000 TWh should be covered till 1985 by conventional thermal power plants.

It is very likely that these revisions had to be corrected to lower values as a consequence of the world wide low economic growth in the last five years.

## 2. Breakdown by source of energy

In 1977, which has been a year with a very high hydroelectric capability factor of 1.22, total gross electricity generation in the countries of the EC has been 1,134.4 TWh, as shown in Figure 2.

864.5 TWh (76.2%) have been generated by conventional thermal power stations, 154.6 TWh (13.6%) by hydroelectric, 112.9 TWh (10.0%) by nuclear power plants and 2.5 TWh (0.22%) by geothermal power plants.

In 1978, total electricity production in the member states of the EC amounted to 1186 TWh, of which 917 TWh (77.3%) produced by conventional thermal power stations, 142 TWh (12.0%) by hydroelectric plants, 125 TWh (10.5%) by nuclear power stations and 2 TWh (0.2%) by geothermic stations.

In Table 1, the electricity generation of the single member states of the EC for the year 1977, according to the energy sources used, is listed.

France and Italy show the highest portion of hydroelectric generation. The values for 1977 are extremely high because of the very high hydroenergy capability factor of 1.28 for France and 1.19 for Italy.

Member states with the highest portion of electricity produced by nuclear reactors in 1977 are Belgium (25.3%), Great Britain (13.1%) and the Federal Republic of Germany (10.8%).

Italy is the unique member state of the EC where electricity is produced by geothermic power stations, the so-called soffioni or blowers (2.501 TWh in 1977).

Member state with the highest portion of electricity produced by conventional thermal power plants in 1977 is Denmark (99.9%), member state with the lowest portion is France (54.0%).

Member state with the highest portion of electricity generation by hard coal combustion is Great Britain (64.9%) together with Denmark (46.5%), whereas Germany (25.9%) and Ireland (22.9%) show the highest portion of electricity produced in 1977 by brown coal or respectively peat combustion.

Ireland (65.0%) and Italy (51.1%) are the member states with the highest portion of electricity generation by combustion of fuel oil.

The Netherlands (76.8%) and Luxembourg (60.5%) show the highest portion of electricity produced by combustion of natural and derived gases.

### 3. Electricity production by conventional thermal power plants

Figure 3 shows electricity production of the EC by conventional thermal power plants according to the various fuels burnt (hard coal, fuel oil, natural and derived gases, brown coal) for the period from 1969 to 1977 together with the hydroelectric capability factor.

Besides small variations due to the hydrocapability factor of a certain year, one can observe the following trends:

- power production by hard coal combustion shows a minimum in the period from 1972 to 1974, from 1975 hard coal combustion is increasing steadily and arrives in 1977 again to the value of 1969. It is to expect, that hard coal combustion (indigenous and imported) in the near future will be the most important fossil fuel in power production in the European Community;
- fuel oil combustion from 1969 to 1973 shows a strong growth and has been nearly duplicated during this period. From the beginning of 1974, petroleum combustion starts to drop down, arriving in 1977 to values similar to that of 1971;
- power production by natural and derived gases has been triplicated in 1974 in comparison to 1969. Beginning from 1975, use of gases in power production shows a slight diminishing trend;
- brown coal combustion for electricity production shows a steady growth for the period from 1960 to 1976, corresponding to the trend of 10 years doubling time. The relative high value of 1976 and the low value of 1977 are to be explained with the big variation of the hydroenergy capability factors for these years and the increasing of nuclear energy production in 1977. As brown coal-fired power plants are used mainly in the basic load range, in years with high hydroelectric energy capacity they can work at lower load.

Table 2 gives an overview on the amounts of fossil fuels in millions of metric tons burnt per year in the countries of the EC by coal- and oil-fired power plants during the period from 1970 to 1978.

Tables 3 and 4 give the amounts in metric tons and the respective calorific equivalent of fossil fuels burnt for power production in the single member states of the EC for the year 1977. Of the 150 millions of tons of hard coal burnt in 1977, the United Kingdom burnt more than half (54.8%) followed by the Federal Republic of Germany (24.0%) and France (13.3%).

93.5% of brown coal burnt in the EC was used in the power plants of the Federal Republic of Germany. Only France and Italy too are using brown coal for power production. Ireland is burning peat ( $3.07 \times 10^6$  tons in 1977) for electricity generation.

Italy (33.2%), Great Britain (21.7%) and France (18.9%) have had the highest consumption of all the fuel oil burnt for power production by the countries of the EC in 1977.

The Netherlands (27.4%) and the Federal Republic of Germany (40.7%) have been the greatest consumers of natural and derived gases for electricity production in the EC in 1977.

In Table 5, the electricity production in 1977 in the single member states by coal and oil fired power stations are listed together with the calculated value of MWh produced in average per each km<sup>2</sup> of territory of each single member state.

This value, of course, may give only a general indication of fossil-fuelled power plants impact in a certain member state. The impact of the single power station on its surroundings depends on specific characteristics of the station, as type of fuel, installed capacity, load factor, abatement technologies installed, geographic situation, etc.

In any case, the values of electricity production by coal and oil fired plants expressed in MWh/km<sup>2</sup> are the highest for the United Kingdom, Germany and Belgium and the lowest for France, Ireland and Luxembourg.

#### **4. Power stations situated in the territory of the European Community**

##### **4.1. Installed capacity**

In Figure 4, the installed capacity of all power stations, conventional thermal, hydroelectric and nuclear, is plotted for the period from 1960 to 1977. For all the period of these last seventeen years, the portion of conventional power plants capacity remained nearly constant, namely about 77%. Until 1977, capacity increase of nuclear power stations compensated the lower increase of hydroelectric power plants capacity.

Table 6 shows the installed capacity of conventional thermal power plants for the year 1976 for the single member states. The sum of the values for the different fuels is more than 100% because there are bivalent and trivalent power stations, which can be operated by two or even three different fuels.

##### **4.2. Conventional thermal power stations in the territory of the European Community**

In the following, the conventional thermal power stations operated in the territory of the nine member states of the EC are listed, indicating their names or location, the

undertaking, their maximum output capacity and the fuels used by each station (3). A geographical map of the main conventional power stations of each member state follows the relative list. Generally, only power stations with an output capacity greater than 250 MW<sub>el</sub> are mapped and indexed with arabic numbers, which correspond to the numbers which precede the name of the power station in the respective list. As can be easily seen from the maps, actually the regions with the highest concentrations of fossil-fuelled power plants are:

- the Ruhr-Aachen region (about 26,000 MW<sub>el</sub> output capacity);
- the zone of Middle England between Liverpool, Leeds, Kingston, Nottingham and Birmingham (about 31,000 MW<sub>el</sub> output capacity);
- the region of London (about 13,000 MW<sub>el</sub> output capacity);
- the triangle Frankfurt-Karlsruhe-Stuttgart (about 7,000 MW<sub>el</sub> output capacity);
- the region of Paris (about 6,500 MW<sub>el</sub> output capacity);
- the Saar territory together with Lorraine (about 4,500 MW<sub>el</sub>);
- Artois (Lille) (about 3,000 MW<sub>el</sub>).

Although the concentration of conventional thermal power plants in the Netherlands is rather high (17,400 MW<sub>el</sub> on the total territory), it has not been taken into consideration in this context because most of the big Dutch power plants at present are operated with natural gas, which means that the emissions of trace metals caused by the fuel, are very low.

On the other hand, all the regions with a relatively high concentration of conventional thermal power plants named above are highly industrialized and populated areas, a truism, but also a fact which is most important in evaluating the potential trace metal pollution caused by coal and oil fired power plants.

It is not in the framework of this report to discuss the location of present or future fossil-fuelled power stations in the EC, although this argument will be one of the most disputed ones in the nearest time. This argument will not be discussed here, also because, besides social-economical reasons, the other emissions from fossil-fuelled power plants (SO<sub>2</sub>, NO<sub>X</sub>, heat) will be of greater weight with regard to the choice of a suitable location for future power plants.

#### 4.3. Forecast for the consumption of fossil fuels by power plants in the EC

The consumption of petroleum products and natural gas, for power production probably will decline in the future, a trend which is already evident by the respective curves for petroleum products and natural and derived gases of Figure 3, which show the decrease of these two fuels for power production beginning from 1974.

The reserves of coal in the Community and in the world are bountiful for a long term. Therefore, coal, in future, should be playing a more important role in the energy supply of the Community. Utilisation of coal, however, is again of a too small importance, partly because of the high production costs of the community coal. But, with the increasing price of petroleum products, coal will result always more able to compete. New technologies such as coal gasification and coal liquefaction, and fluidized bed combustion of coal will accelerate this process.

In their medium-term guidelines for coal 1975 to 1985 of 30 January 1975 (2), the Commission of the European Community came to the result that solid fuels, and in particular hard coal, will be called upon to play an important part as a source of energy for electricity production. The forecast of the European Commission foresees an increasing power station hard coal consumption of about 25% higher compared to 1975, leading to the following estimates of future electricity generation in thermal power stations, as given in Table 7.

Table 7 shows a rise of coal requirements for electricity generation in the EC from 1973 to 1985 of the order of 30 millions tce, the precise tonnage depending primarily on the availability of coal and on the incidence of such environment protection measures may apply during the period. Clearly the power stations coal market in the Community is expanding. On the other hand, it is very difficult to make previsions on the imports of power stations coal from countries outside the EC (mainly USA, South Africa, Poland, Australia, CSR, USSR), depending not only on prices but also on many political factors.

Set-up of energy forecast at present times is a hazardous undertaking. Plausible changes in the basic assumptions concerning economic growth, energy savings and the rate of growth of nuclear and renewable energies would produce very different projections from the ones presented above.

**ANNEX**

During the preparation of this report a very interesting resolution on the medium and long-term perspectives for coal in the Community has been adopted by the European Coal and Steel Community Consultative Committee. Table 8 summarizes the Community's energy requirements in 1977-2000(4).

The pressing need to produce more electrical energy by fossil-fuelled power plants with a greater use of coal may result in increased mobilization of heavy metals by fossil-fuelled power plants with increased contamination hazards for man and the environment.

Because of the complexity of the possible interactions between heavy metals with the environment as well as man, the nature of the risks that the toxic metals mobilize at fossil-fuelled power stations represents is problematic and involves multidisciplinary efforts to establish dose-effect relationships which could serve as a basis in determining the maximum permissible release rate for the environment and maximum permissible doses for man.

Research reports of the JRC on this subject have been divided into a series of five reports with the purpose of examining and evaluating critically the available data giving a list of topics which may serve as a guideline for a research project which should be undertaken to study the EC situation. They are :

Mobilization of heavy metals from fossil-fuelled power plants, potential ecological and biochemical implications

I — Electricity demand, installed capacity and geographical location of the fossil-fuelled power stations in the territory of the European Community;

II — Definition of the problem using a critical path approach, motivation, objectives and research programme to study the European situation;

III — Review of selected elements : V, Ni, As, Se, Mo, Cd, Sb, Hg, Tl, Pb, U;

IV — Analysis of the literature, results, conclusions and recommendations;

V — Natural radionuclides in coals and coal ashes from European conventional power stations and evaluation of a potential environmental impact.

This work is the first of the series and provides a technical basis for the calculations of the minimum and maximum amounts of heavy metals which may be annually mobilized by the conventional power plants of the European Community.
